Impact of Intensive Lifestyle and Metformin Therapy on Cardiovascular Disease Risk Factors in the Diabetes Prevention Program

THE DIABETES PREVENTION PROGRAM RESEARCH GROUP*

OBJECTIVE — The Diabetes Prevention Program demonstrated the ability to delay or prevent type 2 diabetes in participants with impaired glucose tolerance (IGT). Participants with IGT are at high risk for cardiovascular disease (CVD), with a marked increase in the number and severity of CVD risk factors. We prospectively assessed the impact of our interventions on hypertension, dyslipidemia, and CVD events.

RESEARCH DESIGN AND METHODS — The study group consisted of 3,234 individuals with IGT randomly assigned to receive intensive lifestyle intervention, metformin, or placebo. Annual assessment of blood pressure, lipids, electrocardiogram, and CVD events was undertaken.

RESULTS — Hypertension was present in 30% of participants at study entry and then increased in the placebo and metformin groups, although it significantly decreased with intensive lifestyle intervention. Triglyceride levels fell in all treatment groups, but fell significantly more with intensive lifestyle intervention. Total cholesterol and LDL cholesterol levels were similar among treatment groups. Intensive lifestyle intervention significantly increased the HDL cholesterol level and reduced the cumulative incidence of the proatherogenic LDL phenotype B. At 3 years of follow-up, the use for pharmacologic therapy to achieve established goals in the intensive lifestyle group was 27–28% less for hypertension and 25% less for hyperlipidemia compared with placebo and metformin groups. Over an average of 3 years, 89 CVD events from 64 participants were positively adjudicated studywide, with no differences among treatment groups.

CONCLUSIONS — Lifestyle intervention improves CVD risk factor status compared with placebo and metformin therapy. Although no differences in CVD events were noted after 3 years, achieved risk factor modifications suggest that longer intervention may reduce CVD event rates.

RESEARCH DESIGN AND METHODS — The study design and baseline characteristics of the study participants have been reported (13,14). Briefly, 3,234 individuals with IGT were identified for randomization in 27 clinical centers throughout the U.S. Eligibility required a fasting plasma glucose level of 5.3–6.9 mmol/l and a 2-h value after a 75-g glucose load of 7.8–11 mmol/l. The minimum fasting glucose requirement was removed for American-Indian participants. Exclusion criteria included medicines known to alter glucose tolerance, an illness with reduced life expectancy, or inability to participate in physical activity. CVD events were exclusionary if they occurred ≤6 months before randomization.

Eligible participants were randomly assigned to one of three interventions: metformin at a dose of 850 mg twice daily, placebo twice daily, or an intensive program of lifestyle modification. Random treatment assignments were stratified according to clinical center and double blinded for the metformin and placebo groups. The goals of the intensive lifestyle modification program were to achieve and maintain a weight reduction of at least 7% of initial body weight through consumption of a healthy low-calorie, low-fat diet and to engage in physical activity of moderate intensity (such as brisk walking) for at least 150 min/week (15).

A detailed history and physical examination were performed before randomization and annually thereafter. A 12-lead electrocardiogram (ECG) was completed using MACPC-DT ECG acquisition units (Marquette Electronics, Milwaukee, WI) and transmitted to the Electrocardiographic Reading Center (Epicare, Department of Public Health Sciences, Bowman-Gray School of Medicine, Winston-Salem, NC) for classification using the Minnesota code system (16,17). All participants completed a CVD risk status report including updates on family history of CVD as well as interim adverse events. If the participant described a potential CVD event, efforts to obtain hospital records, including all ECGs for review by the central reading center, were undertaken for event classification.

Blood pressure measurements were performed with a standard mercury manometer by certified staff at baseline and quarterly visits using a standard protocol, with the participant seated for at least 5 min before the measurement. A second pressure measurements was obtained 30 s later after complete cuff deflation. The mean of the two measurements was used for analysis. Hypertension was defined as blood pressure ≥140/90 mmHg or the use of antihypertensive medication. Participants meeting the criteria for hypertension were treated according to protocol by either their primary physicians or by clinical site staff, with primary agents being ACE inhibitors, angiotensin receptor blockers, or calcium channel antagonists.

Blood was drawn after a 12-h fast at baseline and annually thereafter. Total plasma cholesterol and triglyceride levels were measured using enzymatic methods standardized to the Centers for Disease Control and Prevention reference methods (18). HDL fractions of cholesterol were measured using dextran sulfate-Mg$^{2+}$ to precipitate all of the apolipoprotein B–containing lipoproteins (19). The LDL cholesterol level was calculated by the Friedewald equation (20) unless the triglyceride level was >4.5 mmol/l, in which case lipoprotein fractions were separated by preparative ultracentrifugation (21) and the LDL subtraction was determined by density gradient ultracentrifugation. Cholesterol was measured in each of 38 fractions using an enzymatic assay (Boehringer, Mannheim, Germany). The LDL cholesterol fractions were pooled, and the LDL cholesterol was determined enzymatically. Relative flotation ($R_f$) was determined by dividing the LDL peak fraction by the total number of fractions (n = 38). The predominance of small-density LDL was defined by the laboratory as $R_f < 0.263$ (10/38). National Cholesterol Education Program Adult Treatment Panel (ATP) II diagnostic criteria for hyperlipidemia (22) were applied to the triglyceride, LDL, and coronary heart disease risk status to determine the classification of participants into normolipidemia, hyperlipidemia requiring diet therapy only, or hyperlipidemia qualifying for drug therapy. Further, participants taking statins, bile acid sequestrants, or fibrates were classified as hyperlipidemic. Elevated LDL was defined as LDL levels of ≥3.4 mmol/l or use of lipid-lowering pharmacologic therapy. Elevated triglyceride was defined as levels ≥2.3 mmol/l or use of lipid-lowering therapy. Hyperlipidemia was defined as meeting criteria for lipid-lowering therapy. Participants and clinical research staff remained blinded to the actual lipid values until drug therapy was indicated.

Events classification
Copies of all ECGs from hospital admissions suspected to be CVD related were collected, and sequential changes indicating differing levels of ECG abnormality were coded according to Minnesota code criteria. Members of the Outcome Adjudication Committee, blinded to treatment assignment, adjudicated all CVD events based upon centrally scored ECG, clinical history, and cardiac enzyme determinations. Silent myocardial infarction was classified by comparing the scheduled annual ECG to the baseline if no prior hospital ECGs had been recorded.

Coronary revascularization included coronary artery bypass surgery or percutaneous angioplasty. Coronary artery disease by angiography was defined as ≥50% stenosis of any coronary artery in the absence of a clinical event and included some participants with inappropriate coronary lesions for revascularization or for whom revascularization failed. Classification of nonfatal stroke included a physician-diagnosed stroke in a patient hospitalized for >24 h. Peripheral arterial

Statistical analysis

Participants were followed for an average of 3.2 years from the start of the study in June 1996 through 31 July 2001, a period 4 months longer than that reported previously (1). This period was chosen to maximize the available data that were collected during the masked phase of the DPP, as unmasking occurred in early August 2001. The report includes all adjudicated events that occurred before 31 July 2001 and were adjudicated by 7 May 2003.

The study design and analysis followed the intention-to-treat principle. CVD event rates among treatment groups were compared using Poisson regression. Fixed-effects models with the assumption of normally distributed errors (23) were used to assess mean differences over time in blood pressure, triglyceride levels, HDL cholesterol levels, and LDL particle size adjusted for the baseline value. Generalized estimating equations (23) were used to assess differences over time in the percentage of participants with categorically defined hypertension and dyslipidemia.

RESULTS — Baseline CVD risk factor characteristics for the cohort (mean age at entry was 51 years) have been previously reported (24,25). Prevalent CVD, hypertension, hypercholesterolemia, and hypertriglyceridemia at entry into DPP are shown by sex in Table 1. The low (<5%) prevalence of CVD may reflect the exclusion of those who had a recent coronary event or reduced life expectancy, as well as a known tendency for selection of healthier participants into a clinical trial.

Nevertheless, a substantial proportion of the participants were at risk for CVD based on the baseline prevalence of hypertension, elevated LDL cholesterol level, or elevated triglyceride levels.

Hypertension was present in 30% of participants at study entry and increased over time in both the placebo and metformin treatment groups (Fig. 1). In contrast, the intensive lifestyle modification group had no significant change in hypertension prevalence, accompanied by significantly decreased lower systolic and diastolic blood pressures, compared with that in the other treatment groups (P < 0.001; Table 2). The use of antihypertensive medications at baseline was 17% in all treatment groups. At 3 years, the point prevalence of antihypertensive pharmacologic therapy is significantly lower (by 27–28%) in the lifestyle group (23%) compared with that in the placebo (31%) and metformin (32%) groups (P < 0.001).

Total cholesterol and LDL cholesterol levels at study entry did not differ significantly among the groups, at 5.3 mmol/l (203 mg/dl) and 3.2 mmol/l (124 mg/dl), respectively. Over time, there were no statistical differences among the placebo, metformin, and intensive lifestyle groups in the overall mean percent change from baseline in either total cholesterol level (−1.2% vs. −0.9% vs. −2.3%, respectively) or LDL cholesterol level (+1.3% vs. +0.3% vs. +0.7%, respectively).

Triglyceride levels fell in all groups, but fell significantly more in the intensive lifestyle group (−0.296 mmol/l [−25.4 mg/dl]) than in the placebo (−0.13 mmol/l [−11.9 mg/dl]) and metformin (−0.08 mmol/l [−7.4 mg/dl]) groups (Fig. 2A). The HDL cholesterol level significantly increased in the lifestyle group (+0.026 mmol/l [+1.0 mg/dl]) compared with the metformin (+0.008 mmol/l or [+0.3 mg/dl]) and placebo.
Furthermore, intensive lifestyle favorably altered the LDL phenotype with a reduction in the prevalence of phenotype B representing a smaller, denser, more atherogenic LDL particle ($P < 0.001$ compared with both placebo and metformin) (Fig. 2C).

At study entry, only 5.2% of participants reported taking pharmacologic therapy for dyslipidemia. Fewer intensive lifestyle participants (12%) required drug therapy for either elevated triglyceride or LDL cholesterol levels by ATP II guidelines at year 3 compared with placebo (16%) or metformin (16%) (Fig. 3).

Only 89 CVD events were confirmed through 31 July 2001 by adjudication over an average of 3 years of follow-up per participant. Neither the cumulative incidence of CVD (percentage of participants suffering an event) nor the event rate (number of events per 1,000 patient years exposed) was different among groups. CVD-related deaths occurred in only four participants in the placebo group, one in the metformin group, and two in the intensive lifestyle group. Nonfatal CVD events occurred in 18 placebo participants (1.7%) with an incidence of 7.3 events per 1,000 patient-years. No statistically significant differences were seen in the metformin group (1.5%, 5.2/1,000 patient-years) or the intensive lifestyle group (2.2%, 9.7/1,000 patient-years) compared with placebo. The small non-significant excess of events in the intensive lifestyle group consisted of CVD hospitalizations and revascularization procedures. Exercise tolerance testing was performed for safety at the time of study entry in those participants randomly assigned to the intensive lifestyle intervention who either had a history of preexisting CVD or were considered to be at high risk for CVD. This increased ascertainment of CVD is supported by five events observed in the first 6 months of the study among the intensive lifestyle group, most of which were revascularization procedures. In addition, study personnel saw participants in the intensive lifestyle group far more often as part of their core curriculum. With the initiation of a physical activity program, case managers were cognizant of the potential exacerbation of CVD. It is possible that the increased activity associated with the intervention differentially unmasked preexisting CVD in this group.

**CONCLUSIONS** — An estimated 10 million persons in the U.S. meet the DPP eligibility criteria for fasting glucose, age, and BMI (26). IGT, although not usually considered a clinical disease in its own
right, is recognized as a risk factor for the future development of both diabetes and cardiovascular disease (27). Stern (28) hypothesized that both stem from a “common soil” of risk factors with variable expression of pathophysiologic changes over time. Meta-regression analysis demonstrates a continuous and positive relationship between 2-h postglucose levels and the subsequent development of CVD (29). When adjusted for covariates such as BMI, blood pressure, and cholesterol, IGT increased the hazard rate for CVD mortality by 34% (30). The National Health and Nutrition Examination Survey (NHANES) II data showed a 42% increased relative risk of all causes of mortality and a 19% increased risk for CVD death among the subset with IGT (31). In NHANES III, however, a cross-sectional association between IGT and nonfatal myocardial infarction and stroke was entirely attributable to traditional CVD risk factors (32). These data highlight the need for a randomized controlled clinical trial such as DPP to better assess causality.

CVD risk factors are typically present in individuals with IGT (33–35). Increased abdominal obesity together with hyperinsulinemia, hypertension, elevated triglyceride levels, and lower HDL cholesterol levels are observed in patients with IGT and constitute the core characteristics of metabolic syndrome as defined by ATP III (36). A recent report from NHANES suggests an overall metabolic syndrome prevalence in the U.S. of ~22% or ~47 million people (37).

The DPP cohort entered the study with prevalence of hypertension of 30%, hypertriglyceridemia of 29%, and hypercholesterolemia of 44%. Annual assessment of these outcomes demonstrated progressive increases in prevalence of hypertension and dyslipidemia in the placebo and metformin groups with attenuation by intensive lifestyle intervention. Aggressive blood pressure management was mandated by protocol, and all treatment groups demonstrated absolute reductions in systolic and diastolic blood pressures; however, intensive lifestyle intervention achieved this with only 5% additionally requiring antihypertensive therapy, compared with 14–15% in the placebo and metformin participants.

Annual assessment of lipids was performed and placed into risk categories according to the ATP II standards applicable at the time. Although mean levels of total cholesterol and LDL cholesterol changed very little during the course of the trial and did not differ among treatment groups, the need for LDL-lowering pharmacologic therapy was significantly less in the intensive lifestyle group compared with that in either placebo or metformin groups (both P < 0.001). Triglyceride levels fell during intensive lifestyle intervention compared with the other treatments, and again participants in this group required less pharmacologic intervention (12% of participants) compared with placebo and metformin (16 and 20.1% with P = 0.03, respectively). The deterioration in lipid levels and blood pressure demonstrated by those in the placebo group reflect the high-risk status of our population with IGT and the lack of efficacy of metformin in modulating that risk.

Reductions in serum triglyceride levels were accompanied by concomitant increases in HDL cholesterol levels and LDL cholesterol size in the intensive lifestyle group, sustained over the course of the study. LDL density, assessed by Rf, was comparable among treatment groups at study entry with mean values at the threshold for the small dense LDL phenotype. Intensive lifestyle intervention caused a prompt increase in LDL size with mean values well into the large buoyant range and a significant (P < 0.001) reduction in the percentage of patients with the proatherogenic phenotype B.

The few CVD events in the DPP did not provide adequate statistical power to test for a significant impact of lifestyle interventions. The ongoing additional 5 years of follow-up in the DPP Outcomes Study will permit additional study of the impact of DPP interventions on CVD events.

In summary, intensive lifestyle intervention reduced known risk factors for CVD including hypertension, high triglyceride levels, low HDL levels, and small dense LDL. Such risk factor modification in other trials (38–41) resulted in substantial reductions in both fatal and nonfatal CVD events, suggesting that prolonged observation of our cohort may ultimately demonstrate a beneficial CVD effect of lifestyle change.
