Objective: This study examines the usefulness of childhood glucose homeostasis variables (glucose, insulin, and insulin resistance index (HOMA-IR)) in predicting pre-diabetes and type 2 diabetes, and related cardiometabolic risk factors in adulthood.

Methods: This retrospective cohort study consisted of normoglycemic (n=1058), pre-diabetic (n=37), and type 2 diabetic (n=25) adults aged 19-39 years who were followed on average for 17 years since childhood.

Results: At least 50% of the individuals who ranked highest (top quintile) in childhood for glucose homeostasis variables maintained their high rank by being above the 60th percentile in adulthood. In a multivariate model, the best predictors of adulthood glucose homeostasis variables were the change in body mass index (BMI) z-score from childhood to adulthood and childhood BMI z-score, followed by the corresponding childhood levels of glucose, insulin, and HOMA-IR. Further, children in the top decile vs the rest for insulin and HOMA-IR were 2.85 and 2.55 times, respectively, more likely to develop pre-diabetes; children in the top decile vs the rest for glucose, insulin, and HOMA-IR were 3.28, 5.54, and 5.84 times, respectively, more likely to develop diabetes, independent of change in BMI z-score, baseline BMI z-score, and total cholesterol/high-density lipoprotein cholesterol ratio. In addition, children with adverse levels (top quintile vs the rest) of glucose homeostasis variables displayed significantly higher prevalences of, among others, hyperglycemia, hypertriglyceridemia, and metabolic syndrome.

Conclusions: Adverse levels of glucose homeostasis variables in childhood not only persist into adulthood but also predict adult pre-diabetes and type 2 diabetes and relate to cardiometabolic risk factors.
Diabetes has become one of the most commonly prevalent chronic diseases and related mortality in the United States (1). There are about 19 million people with type 2 diabetes and another 54 million people with impaired fasting glucose or pre-diabetic state in the country (2). It is also widely recognized that diabetes is a major contributor to adult cardiovascular morbidity and mortality and often accompanies hypertensive renal disease (3).

Type 2 diabetes is preceded by a pre-diabetic state linked to a relative insulin resistance associated with mild increases in blood glucose levels, despite hyperinsulinemia (4). A number of studies have indicated that hyperinsulinemia/insulin resistance is associated with cardiometabolic risk factors including obesity, dyslipidemia, and hypertension, a constellation of disorders characteristic of the metabolic syndrome (5,6). Previous findings, including our own, have shown that the elevations in insulin (7,8) and glucose levels (9-10) persist (track) over time in children and adults alike. We have reported that individuals with relatively high/low fasting plasma insulin levels tended to remain so 8 years later; and significant clustering of obesity, hypertension, and dyslipidemia occurred primarily among those with persistently elevated levels (8). However, information is scant regarding whether the adverse levels of glucose homeostasis variables (glucose, insulin, insulin resistance index) in childhood persist over time and predict pre-diabetes and type 2 diabetes, and other cardiometabolic risk factors in apparently healthy young adults. The present analysis examines this aspect as part of the Bogalusa Heart Study, a biracial (black-white) community-based investigation of the evolution of cardiovascular disease risk beginning in childhood (11).

**RESEARCH DESIGN AND METHODS**

**Study population.** The retrospective study cohort was derived from the two sets of the cross-sectional surveys conducted in the community (65% whites, 35% blacks) of Bogalusa, Louisiana, USA involving 5 cross-sectional surveys of children during 1981 - 1994 (n = 13444; 40% black and 50% female) and 3 cross-sectional surveys of adults during 1995 - 2000 who remained in the community and participated in the study (n = 3640). Subjects (n = 1120; 36% black and 60% female) who participated in their childhood and adulthood and had fasting blood samples on both examinations were included in the study. At the baseline examination, the children with a history of the treatment of diabetes or who had a fasting glucose level >= 100 mg/dL (5.6 mmol/l) were excluded. These subjects were 4 to 18 years of age (mean ± SD age was 11.6 ± 3.6) at baseline and 19 to 39 years at follow-up (mean ± SD age in adulthood was 28.3 ± 5.1). With respect to age, race, sex, overall adiposity (body mass index (BMI) z-score), lipid, glucose, and insulin profile, the baseline childhood characteristics of the study cohort, which represented 8% of the original ascertained childhood population, were similar to the characteristics of the subjects who did not participate in the follow-up survey as adults (data not shown).

According to the American Diabetes Association criteria (12), adult subjects were classified as normoglycemic (n = 1058) if they had a fasting glucose level < 100 mg/dL (5.6
mmol/l); pre-diabetic (n = 37) if fasting glucose level between 100 to 125 mg/dL (5.6 to 6.9 mmol/l); and diabetic (n = 25) if fasting glucose level \( \geq 126 \) mg/dL (7 mmol/l) or under medication for diabetes.

Informed consent was obtained from all participants, and the study was approved by the institutional review board of the Tulane University Health Sciences Center.

General examination

Standardized protocols were used by trained examiners across all surveys (13). Participants were instructed to fast for 12 hours before the venipuncture, and compliance ascertained by an interview on the day of examination. Information on personal health history (eg. hypertension, dyslipidemia, or diabetes and medical treatment for these conditions) was obtained by questionnaires. Anthropometric and blood pressure measurements were made in replicate and mean values were used. Body mass index (BMI (kg/m\(^2\)) = weight in kilograms divided by the square of height in meters) was used as a measure of overall adiposity; waist circumference as an indicator of abdominal visceral fat. BMI z scores for childhood were calculated from the 2000 Centers for Disease Control and Prevention (CDC) Growth Charts to account for the differences in BMIs by sex and age (14). These growth charts express the BMIs of children in the current study relative to their sex and age peers in the United States between 1963 and 1980; BMIs of 5-y-olds in the CDC Growth Charts also include data from 1988-1994. BMI for adulthood were standardized based on age-, sex-specific means and SDs. The calculated z scores are termed “BMI z-score” in the current analyses. Right upper arm length and circumference were used to select the cuff size for blood pressure measurements with mercury sphygmomanometers. Two randomly assigned nurses measured blood pressure (3 replicates each) while subjects were in a relaxed, sitting position. Systolic and diastolic blood pressures were recorded at the first and fourth (children) or fifth (adults) Korotkoff, respectively. Mean arterial pressure (MAP), calculated as diastolic blood pressure plus one third pulse pressure, was used in the analysis.

**Laboratory analyses.** Cholesterol and triglycerides levels were initially measured using chemical procedures on a Technicon Autoanalyzer II (Technicon Instrument) according to the Laboratory Manual of the Lipid Research Clinics Program. Later, these variables were determined by enzymatic procedures on the Abbott VP instrument (Abbott Laboratories) between 1987 and 1996 and on the Hitachi 902 Automatic Analyzer (Roche Diagnostics) afterward. Both chemical and enzymatic procedures met the performance requirements of the Lipid Standardization Program of the Centers for Disease Control and Prevention, which routinely monitors the precision and accuracy of cholesterol, triglycerides, and high-density lipoprotein cholesterol (HDL-C) measurements since the beginning of this study. Serum lipoprotein cholesterol were analyzed by using a combination of heparin-calcium precipitation and agar-agarose gel electrophoresis procedures (15). The intraclass correlation coefficients between the blind duplicate (10% random sample) values ranged from 0.86 to 0.98 for HDL-C, 0.86 to 0.98 for low-density lipoprotein cholesterol (LDL-C), and 0.88 to 0.99 for triglycerides.

From 1976 to 1991, plasma glucose was measured initially by a glucose oxidase method using a
Beckman glucose analyzer (Beckman Instruments). Since then, it has been measured enzymatically as part of a multichemistry (SMA20) profile. Plasma immunoreactive insulin levels were measured by a commercial radioimmunoassay kit (Phadebas, Pharmacia Diagnostics). The intraclass correlation coefficients between blind duplicate values ranged from 0.94 to 0.98 for insulin and 0.86 to 0.98 for glucose. In addition, an index of insulin resistance was calculated according to the homeostasis model assessment formula: HOMA-IR = [insulin (μU/mL) x glucose (mmol/L)/22.5].

Metabolic syndrome risk factors in adults were identified if subjects were centrally obese (waist circumference > 102 cm for male or > 88 cm for female); dyslipidemic (LDL-C >= 160 mg/dL [4.14 mmol/l]), triglycerides >= 150 mg/dL [2.26 mmol/l]), HDL-C < 40 mg/dL [1.03 mmol/l] for males or 50 mg/dL [1.29 mmol/l] for females, or on medication for dyslipidemia); hyperglycemic (fasting glucose >= 100 mg/dL (5.6 mmol/l) or on treatment for diabetes); or hypertensive (>= 130 mm Hg / >= 85 mm Hg or on antihypertensive medication (16). Metabolic syndrome was defined as coexistence of 3 or more of the above risk factors (16).

**Statistical analysis.** All of the statistical analyses were performed with SAS version 9.1 (SAS Institute). Continuous variables were tested for normality using a Kolmogorov-Smirnov test. Values of triglycerides, glucose, insulin, and HOMA-IR variables used in the analyses were log transformed to improve normality. To evaluate the persistence or tracking of elevated levels of glucose, insulin, and HOMA index from childhood to adulthood, the baseline (childhood) age-, race-, sex-specific top quintile for each of these variables was used as a cutoff point to classify children as having abnormal glucose homeostasis variables and to examine the distribution of such children among the corresponding adulthood quintiles 17 years later.

Models assessing the independent relations between childhood cardiometabolic risk factor variables and follow-up (adulthood) levels of glucose, insulin, or HOMA-IR were constructed using a stepwise multiple linear regression. The childhood independent variables initially included in these models were age, race, sex, BMI z-score, BMI z-score change from childhood to adulthood, mean arterial pressure (MAP), ratio of total cholesterol to HDL-C (TC/HDL-C ratio), and glucose (for model 1), insulin (for model 2), and HOMA-IR (for model 3). Since waist circumference in childhood was not measured, BMI z-score values were used as childhood measure of obesity. The ratio of TC/HDL-C was chosen as a measure of dyslipidemia because it is a marker of insulin resistance characteristic of the metabolic syndrome.

A stepwise logistic regression analysis including childhood age, race, sex, BMI z-score, BMI z-score change over time, MAP, TC/HDL-C ratio was then used to determine the odds ratio (OR) and 95% confidence interval (CI) of developing pre-diabetes and diabetes in adulthood on the basis of childhood levels (top decile vs the rest) of glucose and insulin (model 1), and HOMA-IR (model 2). Collinearity was checked in the fixed model. In order to assess the overall fit of the logistic regression model, Hosmer-Lemeshow goodness-of-fit test was performed. Because there was no interaction effect between childhood race (or sex) and glucose (or insulin and HOMA-IR) levels, the race-sex groups
were combined to increase statistical power and to simplify the presentation. Since the prevalence of both pre-diabetes and diabetes in the study cohort was low (< 3.5%) and the alternate analysis using the Cox proportional hazard model gave essentially identical results, only the results of logistic regression analysis estimating the relative risk of diabetes status are presented.

Finally, the prevalence of cardiometabolic risk factors in adulthood was examined according to childhood levels (top quintile vs the rest, specific for age, race, and sex) of glucose and insulin. Significant differences in the prevalence of the metabolic syndrome and its cardiometabolic risk factors in adulthood by childhood glucose, insulin, and HOMA-IR status were tested by the Pearson’s $\chi^2$-test.

RESULTS

The persistence (tracking) of levels of glucose homeostasis variables (fasting glucose, insulin, and HOMA-IR) from childhood to adulthood was examined in terms of persistence of ranking in highest quintiles of the distribution over a 17-year period. If there is no persistence, 20% of those in a given quintile at baseline would persist in that ranking at the follow-up assessment by chance alone. As shown in Fig. 1, more than 32.1% of individuals who ranked highest (in the top quintile) with respect to glucose in childhood also did so in adulthood; another 22.5% remained in the next highest (fourth) quintile. In other words, 54.6% of individuals who ranked highest in childhood tended to maintain their high ranks by being above the 60th percentile in adulthood with respect to glucose, insulin, and HOMA-IR, compared to the non-tracker group (individuals in top quintile at baseline and below the 60th percentile in adulthood), displayed consistently higher BMI z-score at baseline and BMI z-score change after 17-year follow-up ($P < 0.05$), after adjusting for age, race, and sex at baseline; no consistent trend was observed in other cardiometabolic variables (data not shown). With respect to tracking in the lowest quintiles from childhood to adulthood, the trends were essentially the same (data not shown).

As shown in Table 1, based on a stepwise multivariate regression analysis, childhood levels of glucose (model 1), insulin (model 2), and HOMA-IR (model 3) were independent predictors of corresponding follow-up adulthood levels 17 years later. However, as shown by the standardized regression coefficients, the best predictors for adult glucose, insulin, and HOMA-IR levels were the change of BMI z-score from childhood to adulthood and baseline BMI z-score, in that order. The next best predictors for all these variables were the corresponding childhood level, followed by male sex (for glucose and insulin), age (for glucose), and TC/HDL-C ratio (for glucose, insulin, and HOMA-IR), in that order. Overall these variables accounted for 12.5%, 45.4%, and 43.9% of the variance in glucose, insulin, and HOMA-IR, respectively.

As shown in Table 2, among the childhood glucose homeostasis variables, insulin and HOMA-IR (top decile vs the rest) showed odds ratio of 2.85 ($P < 0.05$) and 2.55 ($P < 0.05$), respectively, for developing pre-diabetes after 17 years. In addition, age, baseline BMI z-score, BMI z-score change over time, and TC/HDL-C ratio showed odds ratio of 1.14, $\approx 1.44$, $\approx$
1.85, 1.05, respectively, for developing pre-diabetes (P < 0.05). With respect to developing diabetes, the odds ratios were 3.28 (P < 0.05) for glucose, 5.54 (P = 0.0001) for insulin, and 5.84 for HOMA-IR (P < 0.0001); neither BMI z-score nor BMI z-score change over time predicted the development of overt type 2 diabetes. Further, alternate logistic regression models including age, race, sex, BMI z-score, and BMI z-score change over time, along with either childhood glucose and insulin (model 1) or HOMA-IR (model 2) showed glucose homeostasis variables, BMI z-score, and BMI z-score change over time as significant predictors of adult pre-diabetes and diabetes (P < 0.05). P-values of goodness-of-fit test for all models were > 0.20 (data not shown).

On the basis of glucose homeostasis variable levels (top quintile vs the rest), children were classified into low-risk vs high-risk group and the prevalence rates of obesity, hypertension, dyslipidemia, hyperglycemia, hyperinsulinemia, and metabolic syndrome in adulthood after 17 years of follow-up were compared between the 2 groups (Supplementary Table 1 of the online appendix available at http://care.diabetesjournals.org). The prevalence of adulthood metabolic syndrome and its variables in the high-risk vs low-risk group was significantly greater with respect to hyperglycemia, hypertriglyceridemia (marginal significant in childhood insulin group), hypertension (except childhood glucose group), obesity (except childhood glucose group), low HDL-C (except childhood glucose group), high LDL-C (childhood glucose group only), and metabolic syndrome.

CONCLUSIONS

This community-based study demonstrates that elevated levels of glucose, insulin, and insulin resistance index (HOMA-IR) in childhood track and persist in ranking over a 17-year period. Childhood levels relate independently to corresponding adulthood levels and predict pre-diabetes (except childhood glucose) and diabetes conditions in adulthood, independent of age, race, sex, change in BMI z-score over time, childhood BMI z-score, MAP, and TC/HDL-C ratio. In addition, childhood high vs low-risk status (top quintile vs the rest) with respect to glucose homeostasis variables was associated with increased prevalences of the metabolic syndrome and its component cardiometabolic risk factors. Of particular interest childhood glucose levels clinically considered within the normal range persist into adulthood and can predict diabetes.

The concept of tracking of cardiometabolic risk factors over time is well-recognized. The current findings showing the persistence of adverse levels of glucose homeostasis variables since childhood (7-10), and related predictability of adult pre-diabetes and diabetes conditions are in agreement with previous reports (6,17,18). Bao et al. have demonstrated that the individuals with relatively high/low insulin levels trended to retain such levels over an 8-year follow-up (8). Of those who had insulin levels ranked in the top quartile at baseline, 40% remained so after 8 year (8). Elevations in fasting plasma glucose within the “normoglycemic” range indeed may track from childhood to adulthood and reflect the progression from normal glucose tolerance before the onset of impaired glucose regulation as a continuous process in the development of diabetes (10,18,19).

Of note, gain in adiposity (BMI), a modifiable risk factor, from childhood to adulthood along with childhood adiposity were the best predictors of the adult
glucose homeostasis variables in this study. Because obesity is pathologically linked to insulin resistance/hyperinsulinemia, it plays a crucial role as an initiating factor in the development of dysglycemia. This is consistent with earlier observations showing temporal associations between the degree of baseline adiposity and the incidence of hyperinsulinemia (20) or metabolic syndrome (21), independently of baseline insulin levels. Studies have also shown baseline obesity to be an independent risk factor for type 2 diabetes (6,9,18).

The observational nature of the current study can not address the issue of causality, but only suggests putative mechanisms for the observed relationships. Intra-abdominal and intramyocellular lipid accumulation along with adipocyte derived cytokines have been involved in the development of insulin resistance and the attendant type 2 diabetes (22). It is also apparent from the present study that children with top quintile (high-risk) of glucose, insulin, and HOMA-IR levels displayed increased prevalence of metabolic syndrome and are associated with type 2 diabetes. As mentioned earlier, excess adiposity, especially visceral fat, may be the initiating factor in the observed adverse relationships (21). Excess fat and related insulin resistance/hyperinsulinemia increases triglycerides (very-low density lipoproteins, VLDL) levels as a result of abnormal fatty acid metabolism, excess hepatic triglyceride synthesis and/or reduce clearance of triglycerides from the circulation (23). In turn, increases in LDL-C and decreases in HDL-C levels ensue (24).

With respect to blood pressure, hyperinsulinemia could relate to raises in levels by 1) increasing renal sodium retention, 2) stimulating the sympathetic nervous system, 3) disturbing cell membrane calcium transport, and 4) increasing the smooth muscle cell proliferation (5,25). Alternatively, excess adiposity per se. increases blood pressure by adversely altering, among others, intravascular volume, cardiac output, renal-pressure natriuresis, adipose renin-angiotensin-aldosterone system (25). Taken together, it appears excess levels of glucose homeostasis variables within the “normoglycemic” range even in childhood is a biomarker of risk for developing adverse cardiometabolic conditions including diabetes and subtle abnormalities of the cardiovascular system.

The present study has certain limitations in that it lacks direct assessments of postchallenge glucose, in vivo insulin action and secretion, glycosylated hemoglobin, and body fat mass and distribution. Instead, we used well-established simple surrogate measures of glucose homeostasis that are applicable to population studies. The fasting status for metabolic variables including glucose was based on self-report. However, it should be mentioned that nonsystematic misclassification of self-reports would actually tend to underestimate the outcome. Further, the current findings should be viewed with caution in view of the modest number of events, especially diabetes.

In summary, the present findings indicate the importance of even moderately elevated levels of childhood glucose homeostasis variables (glucose, insulin, HOMA-IR) considered within the “normoglycemic” range in terms of predicting pre-diabetes, diabetes, and metabolic syndrome and it’s cardiometabolic risk factors in apparently healthy young adults, with obesity and the
change of obesity levels over time being the major contributors. Additional longitudinal population-based studies are obviously needed to validate the current findings and to develop the common glucose homeostasis variable cutoff values for type 2 diabetes and other cardiometabolic risks assessment and intervention in pediatric population.
