Regulatory T Cells Preserves β-Cell Function in Type 1 Diabetes in Children

OBJECTIVE—Type 1 diabetes is a condition in which pancreatic islets are destroyed by self-reactive T cells. The process is facilitated by deficits in the number and suppressive activity of regulatory T cells (Tregs). Here, we show for the first time that the infusion of autologous Tregs prolongs remission in recently diagnosed type 1 diabetes in children.

RESEARCH DESIGN AND METHODS—We have administered Tregs in 10 type 1 diabetic children (aged 8–16 years) within 2 months since diagnosis. In total, 4 patients received 10 × 10^6 Tregs/kg body wt and the remaining 6 patients received 20 × 10^6 Tregs/kg body wt. The preparation consisted of sorted autologous CD3^+CD4^+CD25^highCD127^- Tregs expanded under good manufacturing practice conditions.

RESULTS—No toxicity of the therapy was noted. A significant increase in the percentage of Tregs in the peripheral blood has been observed since the day of infusion. These patients were followed along with matched type 1 diabetic patients not treated with Tregs. Half a year after type 1 diabetes onset (4–5 months after Treg infusion), 8 patients treated with Tregs still required <0.5 UI/kg body wt of insulin daily, with 2 patients out of insulin completely, whereas the remission was over in the nontreated group. In addition, plasma C-peptide levels were significantly higher in the treated group as compared with those not treated.

CONCLUSIONS—This study shows that the administration of Tregs is safe and tolerable in children with recent-onset type 1 diabetes.

were sorted to CD3+CD4+CD25(high)CD127(low)− Tregs using combined immunomagnetic/fluorescence-activated technique with the purity of ~100% (median [minimum–maximum] 98% [97–99]). As compared with our previous protocol, important improvements in cell processing were the application of the good manufacturing practice (GMP)-adapted fluorescence-activated cell sorter (FACS) equipped with single-use sample lines (Influx; BD Biosciences, San Jose, CA), which eliminated the risk of cross-contamination, and the application of GMP-grade CellGro medium (CellGenix, Breisgau, Germany) supplemented with 10% autologous serum, interleukin-2 (1,000 units/mL; Proleukin; Chiron, San Diego, CA), and clinical-grade anti-CD3/anti-CD28 beads (Invitrogen, Carlsbad, CA) in 1:1 ratio with cells. Tregs were cultured until the required number was achieved, but for no longer than 2 weeks (median [minimum–maximum]: 10 days [7–14]). Taking all these measures into consideration, we have significantly improved the stability and quality of the Tregs in the final product. The release criteria for Tregs preparation were FoxP3 expression >90% (93% [90–97]), passed interferon (IFN)-γ suppression assay, and negative microbiological tests (no genetic material of hepatitis B virus, hepatitis C virus, or HIV and no microbial contamination in the culture supernatants). Tregs for infusion were washed out completely, suspended in 250 mL 0.9% NaCl (Polfa, Starogard Gd., Poland), and transferred in slow infusion to the patient under anaesthesiological assistance within 1 h of product release.

The administered dose was either 20 × 10^6/kg body wt (n = 6) or when protocol required cessation of Tregs expansion at 2 weeks, 10 × 10^6/kg body wt (n = 4). As control, the other 10 type 1 diabetic patients and their respective matching characteristics were included in the follow-up but did not receive Tregs. The trial was neither blind nor randomized, and the comparison group did not undergo any interventions, such as initial blood drawing for cell processing or mock transfections (comparison of clinical characteristics of the groups provided in Table 1). End points of the study were fasting C-peptide, HbA1c levels, and insulin requirement, with special attention to daily insulin dose (DDI; 0.5 UI/kg body wt) as a borderline for remission in our protocol. The study was conducted according to the protocol approved by the Ethics Committee of the Medical University of Gdańsk (NKEBN/8/2010). Written informed consent was obtained before starting the procedures.

**RESULTS**—No serious infections, episodes of acute hyper- or hypoglycemia, or other adverse effects were observed after the administration of Tregs during the entire follow-up. In one of the patients, the infection was coincident with influenza, which was diagnosed a day after the procedure (confirmed from nasopharyngeal specimen [bioNexia Influenza; bioMérieux, Marcy l’Etoile, France]). The administration of Tregs was followed by a significant decrease in the requirement of exogenous insulin and a decrease in HbA1c levels in all the patients after 2 weeks (Fig. 1 and Supplementary Figs. 2 and 3). In addition, a significant increase in the percentage of Tregs in the peripheral blood were observed since the day of treatment (Wilcoxon test, P = 0.04) (Fig. 2 and Supplementary Figs. 2 and 3).

Significant differences between the study group and the comparison group were noted for the first time half a year after the diagnosis of type 1 diabetes (4–5 months after Tregs administration). Of the 10 patients treated with Tregs, 8 were still in clinical remission, defined as DDI <0.5 UI/kg body wt (DDI median [minimum–maximum] 0.22 UI/kg body wt [0–0.60]), with 2 patients out of insulin completely.

The dose of Tregs administered in our study has a biological meaning because it was able to significantly increase the level of FoxP3+ Tregs in peripheral blood. There were several issues that made our protocol efficacious. In all published trials, immunomagnetic isolation of Tregs was applied, resulting in a maximum of ~60% FoxP3+ T cells in the product, but that figure could be <20% (11,12). So, at least 40% of cells in the product administered to the patients were not Tregs from the beginning. This made it difficult to assess the exact level of administered cells with immunosuppressive activity. With FACS sorting, we reliably achieved ~100% CD3+CD4+CD25highCD127lowFoxP3+ T cells, and in children, >90% of those cells were still FoxP3+ Tregs after expansion. Although FACS sorting is considered a non-GMP procedure, its safety with new sorters is comparable with that of clinical-grade immunomagnetic sorting. In fact, novel single-use fluidic lines preventing cross-contamination and performing the procedure in clean room facilities, together with the resulting purity, make FACS sorting superior to immunomagnetic sorting. Another problem somehow related to the dose assessment is a quality check of the ready-to-administer expanded Tregs product. Proposed in the literature, suppression of the proliferation assay could not be included in release criteria because the result was available 5 days after commencing the assay. In this time period, the suppression of expanded Tregs could change dramatically. Our IFN-γ suppression assay could be included in release criteria, since the results were available within hours, and suppressive activity of the product was confirmed prior to the transfer of Tregs to patients.

There are several limitations of the study involving number of patients and timing. In addition, it is probable that the last initial decrease in the level of HbA1c was very much related to the improvement of the clinical status of the patients and medical interventions other than Tregs infusion. Nevertheless, even at this early 4-month point of our study, when we compare our patients with carefully matched untreated subjects, we already see the difference in the insulin dose and C-peptide levels. Further follow-up, which is under way, will confirm whether this is a sustained remission or only a delay in the destruction of islets.

In our opinion, maneuvers increasing the number of Tregs are safe and tolerable and may potentially control type 1 diabetes. As this study shows, in children with recently diagnosed type 1 diabetes, some improvement in the functioning of β-cells after the infusion of expanded autologous Tregs is a proof of this concept. These results should encourage further investigations involving our novel approach.

Conclusions—As previously described, Tregs from diabetic patients can be effectively expanded (15). However, there were doubts whether autologous Tregs could be effective in the treatment of type 1 diabetes. It is notable that a fraction of IFN-γFoxP3+ Tregs with reduced suppressive efficiency have been described in diabetic patients (16). We could also detect such cells, albeit in a very low proportion in our type 1 diabetic children (~1% of Tregs; data not shown), and they have never affected the results of the suppression assay in vitro. Hence, it might be possible that the majority of defects in type 1 diabetes are related to self-reactive effector T cells, which might be difficult to control by Tregs (17,18). Such activated effector T cells specific for self-islets have been documented recently in humans (19). Fortunately, in NOD mice, the transfer of Tregs could suppress the activity of self-reactive effector T cells and stop diabetes (20). Our study confirms a similar effect of such a Tregs transfer in the human setting.

At the same time, remission was completed in 6 of 10 patients in the comparison group not treated with Tregs (DDI 0.52 UI/kg body wt [0.18–0.69]; Mann-Whitney U test, P = 0.04). In addition, plasma C-peptide levels were significantly higher in patients from the Tregs group as compared with the untreated group (0.75 [0.38–2.11] vs. 0.48 ng/mL [0.15–0.56]; Mann-Whitney U test, P = 0.01) (Fig. 1). No differences were seen between the two doses of Tregs used and, therefore, patients are presented as a single cohort.
