OBJECTIVE—Sleep deprivation is associated with increased risk of adult type 2 diabetes mellitus (T2DM). It is uncertain whether sleep deprivation and/or altered sleep architecture affects glycemic regulation or insulin sensitivity or secretion. We hypothesized that in obese adolescents, sleep disturbances would associate with altered glucose and insulin homeostasis.

RESEARCH DESIGN AND METHODS—This cross-sectional observational study of 62 obese adolescents took place at the Clinical and Translational Research Center and Sleep Laboratory in a tertiary care children’s hospital. Subjects underwent oral glucose tolerance test (OGTT), anthropometric measurements, overnight polysomnography, and frequently sampled intravenous glucose tolerance test (FSIGT). Hemoglobin A1c (HbA1c) and serial insulin and glucose levels were obtained, indices of insulin sensitivity and secretion were calculated, and sleep architecture was assessed. Correlation and regression analyses were performed to assess the association of total sleep and sleep stages with measures of insulin and glucose homeostasis, adjusted for confounding variables.

RESULTS—We found significant U-shaped (quadratic) associations between sleep duration and both HbA1c and serial glucose levels on OGTT and positive associations between slow-wave sleep (N3) duration and insulin secretory measures, independent of degree of obesity, pubertal stage, sex, and obstructive sleep apnea measures.

CONCLUSIONS—Insufficient and excessive sleep was associated with short-term and long-term hyperglycemia in our obese adolescents. Decreased N3 was associated with decreased insulin secretion. These effects may be related, with reduced insulin secretory capacity leading to hyperglycemia. We speculate that optimizing sleep may stave off the development of T2DM in obese adolescents.

Sleep deprivation is endemic: 9.3% of U.S. adults sleep <6 h per night (1), and 75% of high-school seniors report getting insufficient sleep (2). This cumulative societal sleep curtailment is significant, as sleep deprivation is associated with a number of metabolic consequences: increased predisposition to obesity (3) and insulin resistance (IR) (4) in both adults and children, increased risk of type 2 diabetes mellitus (T2DM) in adults (5), and higher fasting glucose in young adults with preexisting diabetes (6). The metabolic consequences of insufficient sleep may be the result of a lack of total sleep or insufficiency of a certain sleep component. The American Academy of Sleep Medicine recognizes four different sleep stages indicated as follows: stage 1 (N1), a brief transition between wake and sleep; stage 2 (N2); stage 3 (N3), “slow-wave” or “deep” sleep; and rapid eye movement (REM) (dream) sleep. In adult studies, cerebral glucose utilization declines (7) and plasma glucose rises (8) in N3 sleep. One pediatric study found a negative association between REM sleep duration and obesity (9), but there is little pediatric data on sleep architecture and glucose and insulin homeostasis. A potential confounding factor is obstructive sleep apnea (OSA), a syndrome more common in obesity in which upper airway obstruction leads to sleep fragmentation and desaturation (10). OSA has been associated with T2DM risk in adults (10) and with IR in children (11,12). We hypothesized that in obese adolescents (who are at risk for T2DM), altered sleep architecture is associated with abnormalities of insulin secretion and sensitivity and of glucose homeostasis independently of confounding factors (e.g., degree of obesity, presence of OSA, sex, and pubertal stage). Therefore, the aim of our study was to investigate the relationship between sleep architecture and insulin secretion and sensitivity and overall glycemia in this population.

RESEARCH DESIGN AND METHODS—This was a cross-sectional study of obese (BMI, >95th percentile for age and sex) pubertal adolescents recruited from an obesity clinic in The Children’s Hospital of Philadelphia. Exclusion criteria included having previously diagnosed diabetes or sleep disorders, genetic syndromes affecting glucose tolerance or sleep, or major organ system illness, or taking medications affecting insulin or glucose metabolism. The protocol was approved by The Children’s Hospital of Philadelphia Institutional Review Board; informed consent was obtained from the parents or guardians, and assent was obtained from the participants.
**Sleep and glucose and insulin homeostasis**

**Anthropometrics**
Demographic data and medical history were obtained from guardians and participants. Physical examination, including pubertal (Tanner) staging, was performed by a study investigator. Weight was measured using a digital scale (Scaletronix, White Plains, NY). Height was measured using a wall-mounted stadiometer (Holtain Inc., Crymych, U.K.). BMI was calculated as weight (kilograms) divided by height (meters) squared. BMI percentiles and z scores were assessed using age- and sex-specific reference data (13).

**Glucose and metabolic testing**
After a 12-h overnight fast, an oral glucose tolerance test (OGTT) was performed: subjects ingested oral glucose solution (1.75 g/kg, maximum 75 g), and blood samples for glucose and insulin were obtained at –10, 0, 10, 30, 60, 90, 12, 150, and 180 min. Hemoglobin A1c (HbA1c) was also measured. The following morning, after an overnight fast, subjects underwent a frequently sampled intravenous glucose tolerance test (FSIGT): infusion of 0.25 g/kg of 25% dextrose intravenously over 30 s, infusion of regular human insulin (0.015 units/kg i.v.) over 5 min at t = 20 min, and drawing of blood samples for glucose and insulin at t = −5, 2, 4, 8, 19, 22, 30, 40, 50, 70, 100, and 180 min. Plasma glucose levels were measured by the glucose dehydrogenase method (Hemocue Analyzer; Hemocue Inc., Cypress, CA). Plasma insulin levels were measured by radioimmunoassay (LINCO, St. Charles, MO). The MINMOD Millenium software program (14) was used to estimate indices of glucose and insulin dynamics from the FSIGT.

**Calculated insulin sensitivity and secretion parameters**

**A. OGTT**

1. Homeostasis model assessment of IR (HOMA-IR) is a validated measure of insulin sensitivity (15):

   \[
   \text{HOMA-IR} = \frac{\text{fasting plasma insulin (mIU/mol)} \times \text{fasting plasma glucose (mmol/L)}}{22.5}
   \]

2. Insulinogenic index (IGI) is a measure of insulin secretion that has been validated in children against the hyperglycemic clamp (16):

   \[
   \text{IGI} = \frac{[30\text{-min insulin} - \text{FPI (mIU/mL)}}{[30\text{-min glucose} - \text{FPG (mg/dL)}]
   \]

3. Whole-body insulin sensitivity index (WBISI) is an insulin sensitivity measure that has been validated in obese children and adolescents (15):

   \[
   \text{WBISI} = \frac{10,000}{("\text{fasting glucose}\times\text{fasting insulin})} \times("\text{mean glucose}\times\text{mean insulin})
   \]

   Higher WBISI levels indicate greater insulin sensitivity.

**B. FSIGT**

1. Acute insulin response to glucose (AIRg) is a parameter of early pancreatic response to glucose, calculated as the mean incremental plasma insulin concentration over baseline in the first 8 min of the FSIGT (14).

2. Sensitivity to insulin (SI) is a parameter of early pancreatic insulin secretion.

**Overnight polysomnography**
Overnight polysomnography (PSG) was performed the night between the OGTT and FSIGT. Signals were recorded on a computerized system (Rembrandt; Rescare, Buffalo, NY). The following parameters were recorded: electroencephalogram (C3/A2, C4/A1, O1/A2, and O2/A1); right and left electro-oculograms; tibial electromyogram; chest and abdominal wall motion by inductance plethysmography; oronasal pressure airflow (nasal pressure cannula with oral thermistor bead; Pro-Tech, Woodinville, WA); end-tidal PCO2, measured at the nose by infrared capnometry (Nellcor N-1000); arterial oxygen saturation (SaO2) by pulse oximetry, and oximeter pulse waveform. Studies were reviewed by a single sleep Board-certified investigator (L.J.B.), who had no knowledge of subjects’ metabolic status. Sleep architecture (N1, N2, N3, and REM sleep stages) and respiratory disturbances (including the apnea-hypopnea index [AHI], arousal index, and lowest oxyhemoglobin saturation [lowest SaO2]) were scored using standard pediatric criteria (17).

**Statistical analysis**
Statistical analysis was performed using SPSS Statistics 17.0 analysis software. Histograms and one-sample Kolmogorov-Smirnov tests were used to assess normality of distribution of continuous variables. Distributions of seriously skewed variables were normalized via logarithmic transformation. Pearson or Spearman correlations were used to examine associations between sleep architecture or OSA measures and parameters of glucose homeostasis and insulin secretion and sensitivity. Hierarchical linear regression procedures were used to evaluate the aforementioned relationships while controlling for potential confounding variables (e.g., degree of obesity and OSA). Covariate selection for the stepwise regression stages was guided by correlation analyses. Assumptions of linearity were tested by examining plots of

the standardized residuals as a function of standardized predicted values. Where curve estimation procedures uncovered curvilinear relationships, polynomial regressions were conducted. Analysis of covariance (ANCOVA) models were used to examine differences in the outcome variables between sexes and among different pubertal stages, controlling for covariates. As we tested three underlying hypotheses relating to the relationship between sleep architecture and insulin secretion and sensitivity and overall glycemia, we used an adjusted $P$ value of $<0.017$ ($0.05/3$) for statistical significance.

## Results

### Study subjects

Seventy obese adolescents were screened for participation; seven cancelled prior to the study date and one did not undergo PSG, leaving 62 participants for analysis. Baseline subject characteristics are presented in Table 1. Insulin and glucose values, calculated indices, and PSG results are presented in Table 2.

### Sleep and glucose homeostasis

Total sleep time (TST) was significantly or near-significantly associated with both short- and long-term measures of glucose homeostasis (Table 3). Curve estimation modeling and regression statistics showed that these relationships were U shaped (quadratic) (Fig. 1A–C). There was no association between any measure of OSA and measures of glucose homeostasis (Supplementary Table 1).

On regression analysis, TST was the most significant predictor of glucose homeostasis measures. Individual sleep stages, pubertal stage, and sex were not significant predictors of any glucose homeostasis measure; BMI z score was a significant contributor, and Tanner stage was a marginal contributor, to the overall 2-h glucose model only (not to the overall fasting glucose or HbA1c models). Sex did not contribute significantly to any glucose model.

For the overall regression models mentioned above, adjusted $R^2$ and $P$ values were as follows: 0.201 ($P = 0.002$) for fasting glucose, 0.442 ($P < 0.0005$) for 2-h glucose, and 0.200 ($P = 0.002$) for HbA1c.

### Sleep and insulin secretory measures

N3 sleep, both total duration and the percentage of total sleep time in N3 (%TST in N3), correlated significantly or with marginal significance ($P$ value between 0.017 and 0.05) with several insulin secretory measures (Table 4) in bivariate analysis. Curve estimation modeling uncovered a cubic relationship between N3 and AIRg ($r^2 = 0.286$; $P = 0.001$), with inflection points at approximately 65 and 98 min. OSA measures did not associate significantly with any measure of insulin secretion (Supplementary Table 2). A marginally significant negative association was seen between pubertal stage and both N3 duration ($r = −0.282$; $P = 0.028$) and %TST in N3 ($r = −0.252$; $P = 0.050$), but there was no association between pubertal stage and any of the insulin secretory measures examined, or between sex and insulin secretory measures.
N3 duration remained the strongest predictor of insulin secretory measures on stepwise regression analysis. Other sleep stages, TST, OSA measures, and sex were not significant predictors of insulin secretory measures in the final regression model. BMI z score contributed significantly to the Airg-final model but not to the IGI model, and pubertal stage contributed significantly to the final IGI model but not the Airg model. Adjusted $R^2$ and $P$ values for the overall models were 0.161 ($P = 0.002$) for IGI and 0.383 ($P < 0.0005$) for Airg.

**Sleep and insulin sensitivity**

Correlation analysis showed a marginally significant negative association between N2 sleep and several insulin sensitivity measures (Table 4). A marginally significant negative correlation was seen between AHI and $S_1 (r = -0.338; P = 0.025$; see Supplementary Table 3). Pubertal stage and sex did not associate significantly with any insulin sensitivity measure. However, on regression analysis, no strong associations were seen between sleep architecture or OSA and OGTT-derived insulin sensitivity measures. We found a marginal relationship between N2 duration and HOMA-IR (overall $R^2 = 0.088; P = 0.040$), and although the relationship between %TST in N2 and $S_1$ was stronger, BMI z score (i.e., degree of obesity) was the strongest predictor in that model (overall model $R^2 = 0.400; P < 0.0005$).

**CONCLUSIONS**—In this multiethnic group of obese adolescents, we found strong relationships between sleep, hyperglycemia, and insulin secretion. Specifically, we found U-shaped relationships between total sleep duration and measures of both short- and long-term glycemia, and positive or cubic associations between N3 and insulin secretory measures, even after adjusting for potential confounders such as degree of obesity, OSA, sex, and pubertal stage. Our sleep duration data suggest that glucose metabolism is optimal when 7.5–8.5 h of sleep is achieved. This is consistent with adult data noting U-shaped associations between self-reported sleep duration and T2DM risk (5).

Adults with T2DM have also been reported to have shorter N3 duration than nondiabetic adults (18). Although one postulated mechanism suggests that N3 loss increases IR (19), our results instead demonstrated a relationship between N3 and insulin secretion. This relationship, which appeared to be a function of N3 itself rather than of total sleep duration,
Sleep architecture (durations are given in minutes; percentages are denoted as %). All numbers represent correlation coefficients. Numbers in italics indicate near-significance ($p < 0.05$), while boldface indicates significance ($p < 0.01$).
