Objective . To investigate the long-term associations of magnesium intake with incidence of diabetes, systemic inflammation and insulin resistance among young American adults.

Research design and methods . A total of 4,497 Americans, aged 18-30 years, who had no diabetes at baseline, were prospectively examined for incident diabetes based on quintiles of magnesium intake. We also investigated the associations between magnesium intake and inflammatory markers, i.e., high-sensitivity C-reactive protein (hs-CRP), interleukin-6 (IL-6), and fibrinogen, and the homeostasis model assessment of insulin resistance (HOMA-IR).

Results. During 20-year follow-up, 330 incident diabetic cases were identified. Magnesium intake was inversely associated with incidence of diabetes after adjustment for potential confounders. The multivariable-adjusted hazard ratio of diabetes for participants in the highest quintile of magnesium intake was 0.53 (95% confidence interval, 0.32–0.86; $P_{\text{trend}} < 0.01$) compared with those in the lowest quintile. Consistently, magnesium intake was significantly inversely associated with hs-CRP, IL-6, fibrinogen, and HOMA-IR; and serum magnesium levels were inversely correlated with hs-CRP and HOMA-IR.

Conclusions. Magnesium intake was inversely longitudinally associated with incidence of diabetes in young American adults. This inverse association may be explained, at least in part, by the inverse correlations of magnesium intake with systemic inflammation and insulin resistance.

Although obesity is an important risk factor for diabetes, certain foods or nutrients may also be associated with an increased risk of diabetes (1). Magnesium, found in whole grains, is an essential cofactor for multiple enzymes involved in glucose metabolism (2). Several cohort studies have investigated magnesium intake in relation to risk of diabetes, but the findings have been inconsistent (3). Some (4-6), but not all (7-9), studies found an inverse association between magnesium intake and diabetes risk. Of note, all previous studies except one (7) used self-reported cases and all studies were conducted among middle-aged or elderly people.

In addition, the pathophysiological mechanisms underlying the beneficial effects of magnesium intake on diabetes are not fully understood. Cross-sectional studies have suggested an inverse correlation between magnesium intake and inflammatory markers (10,11), and some clinical and experimental

studies have suggested magnesium may improve insulin sensitivity (12,13). Therefore, we investigated magnesium intake in relation to the incidence of diabetes in a large cohort of young American adults participating in the Coronary Artery Risk Development in Young Adults (CARDIA) study. To explore possible mechanisms, we also examined whether magnesium intake is inversely associated with systemic inflammation markers, i.e., high-sensitivity C-reactive protein (hs-CRP), interleukin-6 (IL-6), and fibrinogen, and with the homeostasis model assessment of insulin resistance (HOMA-IR).

RESEARCH DESIGN AND METHODS

The CARDIA study is an ongoing, multicenter, prospective cohort study investigating the role of lifestyle and other factors in the development of risk factors for cardiovascular diseases among young adults (14). Briefly, 5,115 African American and Caucasian men and women, aged 18-30 years, were enrolled from 1985 to 1986. To date, six

follow-up examinations have been completed. The average follow-up rate was 94.1%, and approximately 70% of participants in the original cohort completed the follow-up examination at year 20 (2005–2006).

For analyses, we excluded participants who had taken anti-diabetic medications and/or had a fasting plasma glucose ≥ 7 mmol/l at baseline (n=35); those who did not participate in any follow-up examinations (n=204); those who had missing data on magnesium or total energy intake, or who reported implausible total energy intake (<800 or >8000 kcal/d for men; <600 or >6000 kcal/d for women, n=74); and women who were pregnant at any examination (n=233). We further excluded participants who had missing data on smoking status (n=33), alcohol consumption (n=18), physical activity (n=1), body mass index (BMI; n=14), or waist circumference (n=6). After these exclusions, a total of 4,497 participants (87.9% of 5,115) remained in the analyses.

All participants gave written informed consent. The study design, data collection, and analyses were approved by the institutional review boards of the centers involved.

Assessment of magnesium intake and other dietary factors. The details of dietary assessment and validation of magnesium intake in CARDIA have been described previously (15). Briefly, we collected dietary data, including magnesium intake at baseline and exam years 7 and 20, using a validated interviewer-administered CARDIA Diet History Questionnaire (16). Information on supplement use was also collected. Magnesium intake represented the sum of dietary magnesium intake and magnesium supplement.

Measurement of other covariates. Age, gender, ethnicity, years of education, smoking status, and alcohol consumption were self-reported, obtained by interview or self-administered questionnaire. Smoking status

was classified as never, former, and current. Alcohol consumption was classified into four groups based on daily amount ingested: none, 0.1–9.9, 10–19.9, and ≥ 20 g/d. BMI was calculated as weight (kg) divided by height squared (m^2) and was classified into three groups: <25, 25–29.9, and ≥ 30 kg/ m^2 (17). Waist circumference was measured at the maximum abdominal girth, and all anthropometric measures were taken in duplicate and averaged. Three measurements of resting systolic and diastolic fifth-phase blood pressures were taken using a random-zero sphygmomanometer. The average of the second and third measurements was used in the analyses. Physical activity was assessed using the interview-based, validated, CARDIA Physical Activity History Questionnaire (18). A score of 100 exercise units is approximately equivalent to participation in vigorous activity for 2–3 hours/week during 6 months of the year. Family history of diabetes was defined as either mother or father having diabetes.

Assessment of inflammatory markers, HOMA-IR, OGTT, and A1C. Serum hs-CRP was measured at years 7, 15, and 20, with a nephelometry-based high throughput assay. Intra- and inter-assay coefficients of variations (CVs) were 2.3–4.4% and 2.1–5.7%, respectively. IL-6 was analyzed at year 20 using a High Sensitivity ELISA assay. A routine CV was 6.3%. Fibrinogen was assessed at years 5, 7, and 20 by the Clauss method (year 5) and a BNII nephelometer (year 7 and 20) calibrated with standard normal plasma (19). Intra- and inter-assay CVs were 2.7% and 2.6% at year 7 and 3.1% and 4.2% at year 20. Fasting plasma glucose and insulin levels were determined by the hexokinase ultraviolet method and radioimmunoassay, respectively, at years 0, 7, 10, 15, and 20. Masked analysis of split serum samples resulted in a technical error of 16.6 % for mean insulin levels ($r = 0.98$). Between-method correlation was 0.83. HOMA-IR was calculated as glucose (mmol/l) \times insulin

(mU/l)/22.5 (20).

Two-hour plasma glucose levels were measured from a standard 2-hour oral glucose tolerance test (OGTT) at years 10 and 20. Glycosylated hemoglobin (A1C) was assessed using a Tosoh G7 high performance liquid chromatography instrument at year 20. The inter-assay CVs were 2.0-3.0%.

Ascertainment of diabetes. Participants with one or more of the following were determined to have diabetes: 1) fasting plasma glucose ≥ 7.0 mmol/l (years 0, 7, 10, 15, and 20); 2) non-fasting plasma glucose ≥ 11.1 mmol/l (years 0, 7, 10, 15, and 20); 3) postprandial 2-hour plasma glucose ≥ 11.1 mmol/l from an OGTT (years 10 and 20); 4) A1C $\geq 6.5\%$; (year 20) or 5) reported use of anti-diabetic medications (all examinations), which were verified by medication names (21).

We could not clearly distinguish diabetes type, because some participants were young at diagnosis and used insulin as treatment. Therefore, we used the term “diabetes” rather than “type 2 diabetes”, but the great majority of cases were type 2 diabetes.

Statistical analysis. Participants were divided into quintiles according to magnesium intake (mg/1000 kcal). Baseline characteristics of participants were calculated as mean and standard deviation, median and inter-quartile range, or percentage and were compared according to quintiles of magnesium intake using analysis of variance, Kruskal-Wallis test, or chi-square test as appropriate.

We used the Cox proportional hazards model to estimate the hazard ratios (HRs) and 95% confidence intervals (CIs) of incident diabetes. Follow-up time was calculated as the difference between the baseline examination and the year in which diabetes was first identified, year 20, or the year a participant was censored. To best represent long-term dietary intake and to minimize measurement error and the effect of diagnosed diabetes or other conditions on diet,

we used only baseline magnesium intake in relation to cases identified at years 2, 5, and 7, and used the average magnesium intake of baseline and year 7 in relation to cases occurring at years 10, 15, and 20 (15). If year 7 data were missing, we imputed by multiplying baseline magnesium intake and the ratio of the mean values at two exams. In addition, since the cut-off point of fasting glucose for defining diabetes was changed from 140 mg/dl to 126 mg/dl in 1997, we used a cut-off point of 140 mg/dl at year 0, 7 and 10 in sensitivity analysis to test the robustness of our results.

The initial analysis (model 1) was adjusted for age, gender, ethnicity, and study center. In model 2, we further adjusted for education, smoking status, alcohol consumption, physical activity, family history of diabetes, BMI, systolic blood pressure, and total energy intake. In model 3, we additionally adjusted for dietary intake of saturated fat and crude fiber. Continuous variables using the median value in each quintile were created for trend tests.

In addition, we tested for possible interactions between magnesium intake and gender, ethnicity, family history of diabetes, and BMI, by adding corresponding multiplicative interaction terms in the models, followed by the likelihood ratio test. We also stratified the data according to these variables to determine whether they modified the associations.

We examined the association between magnesium intake and serum levels of inflammatory markers and HOMA-IR. A logarithmic transformation was used to improve the normality of hs-CRP, IL-6, fibrinogen, and HOMA-IR distributions. Because hs-CRP, fibrinogen, and HOMA-IR were measured multiple times, generalized estimating equations (GEEs) with exchangeable correlation structure for simplicity were used. Analogous to the accumulative diet method used in the Cox

models, we used the average magnesium intake of years 0 and 7 for all repeated measures that occurred at years 10, 15, or 20. As IL-6 was measured once, the general linear model (GLM) was used. The adjusted covariates in the models were the same as those listed in Table 3.

We examined the correlation between serum and magnesium intake at year 20 and also analyzed the relations between serum magnesium and inflammatory markers and HOMA-IR using GLM, after adjusting for covariates in the same year in the manner described above.

All analyses were performed with SAS 9.1.3 (SAS Institute, Inc., Cary, NC, USA). A value of $P < 0.05$ was considered as statistically significant.

RESULTS

Baseline characteristics of 4,497 participants according to quintiles of magnesium intake are shown in Table 1. Compared with participants in the lowest quintile of magnesium intake, those in the highest quintile were slightly older and more likely to be female, Caucasian, and non-current smokers. They also had lower BMI and waist circumference, and were less likely to have a family history of diabetes. In addition, they had higher rates of magnesium supplement use and crude fiber intake and lower intakes of total energy and saturated fat. The correlation coefficients of total magnesium intake with magnesium supplementation and whole grain consumption were 0.58 and 0.25 at year 0, and 0.71 and 0.25 at year 7 (all $p < 0.001$).

During the 20-year follow-up, 330 incident cases of diabetes were identified, including 212 cases determined by fasting glucose criteria and 3, 37, 35 and 43 cases determined by non-fasting glucose, 2-hour glucose after OGTT, A1C and anti-diabetic medication use criteria, respectively. Magnesium intake was inversely associated

with incidence of diabetes. The incidence of diabetes was 47% lower (HR=0.53; 95% CI, 0.32–0.86; $P_{\text{trend}} < 0.01$) for participants in the highest quintile compared to the lowest quintile, after adjustment for age, gender, ethnicity, study center, and other potential confounders (Table 2). When stratified data according to magnesium supplementation, the observed inverse associations were generally consistent, but were somewhat attenuated among supplement non-users because that the range of magnesium intake was substantially narrowed (Table 2).

When we substituted waist circumference for BMI in model 3, a similar inverse association was observed (HR=0.59; 95% CI, 0.36–0.98; $P_{\text{trend}} = 0.04$). Also, when we used different definitions of diabetes based on the time period of the exam, a total of 327 incident cases of diabetes were identified. These results were essentially the same as findings from the primary analysis (data not shown).

In addition, we examined a few food groups that are rich in magnesium. These associations were qualitatively consistent with magnesium intake. For example, the multivariable-adjusted HRs (95% CIs) of incident diabetes were 1.00, 1.26 (0.93–1.71), 0.82 (0.57–1.17), 0.71 (0.48–1.04), and 0.81 (0.55–1.20) ($P_{\text{trend}} = 0.03$) across quintiles of whole grain consumption.

By stratifying data according to gender, ethnicity, family history of diabetes, and BMI, respectively, the observed inverse associations were more pronounced in females, overweight individuals, those without family history of diabetes. However, none of the tests for interactions among these variables showed statistical significance (Figure 1).

Magnesium intake was also inversely associated with hs-CRP, IL-6, and fibrinogen levels after adjustment for potential confounders. Moreover, a significant inverse association between magnesium intake and

HOMA-IR was observed (Table 3). Furthermore, although the Spearman correlation coefficient between serum and total magnesium intake at year 20 was 0.07, serum magnesium levels were significantly inversely correlated with hs-CRP and HOMA-IR (Online Appendix Table available at <http://care.diabetesjournals.org>).

CONCLUSIONS

In this longitudinal study, we found a significant inverse association between magnesium intake and incidence of diabetes in young American adults. Our findings are generally consistent with results from some previous studies (1,4-6). Conversely, three other studies found no significant associations between magnesium intake and risk of diabetes (7-9), though one of these reported that a low serum magnesium level was a strong, independent predictor of incident type 2 diabetes (7). Of note, in a meta-analysis of cohort studies (3), the pooled relative risk of type 2 diabetes per 100 mg/day increment of magnesium intake was 0.85 (95% CI, 0.79–0.92).

We observed an inverse association between magnesium intake and HOMA-IR. This finding indicates that the beneficial effects of magnesium intake on risk of diabetes may be partially due to magnesium's role in improving insulin sensitivity (2,8,22), and suggests that low magnesium intake and insulin resistance may detrimentally influence each other. Magnesium is important as a second messenger for insulin action. Reduced intracellular magnesium concentration may result in defective tyrosine kinase activity during insulin signaling and decreased insulin sensitivity (12,13). Moreover, insulin itself is an important regulatory factor for intracellular magnesium accumulation (12).

An inverse association between magnesium intake and hs-CRP level was reported in three cross-sectional studies (10,11,23). Also, an inverse association

between magnesium intake and IL-6 level was found in one (23), but not in another study (11). In the present study, magnesium intake was inversely associated with levels of hs-CRP, IL-6, and fibrinogen, and serum magnesium was inversely associated with hs-CRP levels. These findings support another possible pathway for altering systemic inflammation and may explain, at least in part, the potential beneficial effect of magnesium intake on diabetes risk.

The strengths of our study include a long-term follow-up period, a large sample size of young adults, and a sample well balanced for gender and ethnicity. Most previous findings are from studies in middle-aged or elderly people, who were likely to have already had disease onset and may have made lifestyle changes for disease prevention or treatment. Furthermore, we longitudinally measured several inflammatory markers and fasting insulin level (HOMA-IR), which enabled us to explore potential pathophysiological mechanisms for the beneficial effects of magnesium intake on diabetes risk. Moreover, we defined diabetes based mainly on fasting and postprandial glucose levels from an OGTT and A1C measurements, in addition to a self-reported questionnaire. In previous studies (4-6,8,9), except the ARIC study (7), all diabetes cases were self-reported. Our study was further strengthened by our consistent findings across dietary magnesium intake, serum magnesium level, and consumption of whole grains – a major source of magnesium.

Our study also had limitations. First, the possibility of confounding from unknown or unmeasured factors can not be completely ruled out. Particularly, participants in the highest quintile of magnesium intake were most likely to take supplements, meaning that these participants may be more health-conscious and therefore different from participants in other groups. However, our results are unlikely to be substantially biased

given our extensive data analysis, consistent findings in sensitivity analysis (e.g., stratified analysis based on supplementation) and supportive biological mechanisms. Second, there is inherent limitation in dietary assessment of individual nutrients including magnesium. Thus, observed associations are likely to reflect consumption of foods rich in magnesium such as whole grains, nuts, legumes, fruits and vegetables, but may not be the result of an isolated effect of magnesium intake. Third, although the inverse association of magnesium intake with inflammatory markers reminded after further adjusting for some health conditions including asthma and serum cholesterol levels, we could not fully control for all possible sources of systemic inflammation (e.g., acute infection) because of lack of information. Fourth, lack of fasting glucose data for years 2 and 5 may have resulted in underestimation and misclassification of diabetes at these times. However, this limitation should not substantially bias our results, as diabetes incidence was relatively low for these years, when most participants were in their 20s, and many of those who were diagnosed between years 0 and 7 would have been detected at year 7 or later.

A recent clinical trial suggested that magnesium supplementation improves insulin sensitivity in hypomagnesemic non-diabetic participants (24). In a crossover trial among healthy individuals, magnesium supplementation inhibited fat absorption and decreased postprandial triglycerides levels (25). In our data, total magnesium intake was important regardless of its source. Therefore, increasing magnesium intake may important for improving insulin sensitivity, reducing systemic inflammation, and decreasing diabetes risk.

In conclusion, magnesium intake was inversely associated with incidence of diabetes. The potential beneficial effects of magnesium intake on the risk of diabetes may be explained by magnesium's favorable effects on systemic inflammation and insulin resistance. Further large-scale clinical trials are needed to establish causal inference and elucidate the mechanisms behind this potential benefit.

SBP, mmHg	111.2 (10.8)	111.5 (11.2)	110.8 (10.9)	109.9 (10.2)	109.2 (11.3)	<0.01
DBP, mmHg	68.2 (10.2)	68.8 (10.2)	69.2 (9.5)	68.8 (9.0)	68.2 (9.3)	0.11
Total energy intake, kcal	3,264 (1,650)	3,170 (1,571)	2,943 (1,363)	2,652 (1,189)	2,374 (1,127)	<0.01
Total saturated fat, g	53.4 (31.3)	51.6 (28.3)	47.8 (25.0)	42.3 (21.6)	35.2 (20.6)	<0.01
Crude fiber, g	4.7 (2.9)	5.4 (3.0)	5.6 (3.1)	6.0 (3.2)	6.7 (4.0)	<0.01
Whole grain, times/week	4.9 (7.3)	7.4 (8.6)	9.7 (9.7)	11.0 (9.5)	13.1 (11.1)	<0.01
Magnesium supplementation, mg	1.6 (9.4)	4.0 (15.7)	9.5 (25.2)	17.9 (35.9)	69.4 (137.1)	<0.01

Data are mean (SD), or %. SBP, systolic blood pressure; DBP, diastolic blood pressure. P values are for any difference across the quintiles of magnesium intake using analysis of variance, Kruskal-Wallis test, or chi-square test as appropriate.

Table 2. Hazard ratios (95% confidence intervals) for incident diabetes according to total magnesium intake quintiles

	Quintiles of total magnesium intake					<i>P</i> for trend*
	1 (lowest)	2	3	4	5 (highest)	
Total cohort (n=4,497)						
Magnesium intake, mg/1000 kcal; Median (interquartile range)	99.9 (91.7-106.1)	121.0 (116.5-125.2)	140.1 (134.8-145.5)	162.1 (155.8-169.3)	201.5 (187.7-233.3)	-
No. of events / participants	81 / 899	85 / 900	77 / 899	52 / 900	35 / 899	-
Model 1	1.00	0.95 (0.70-1.30)	0.91 (0.66-1.26)	0.63 (0.43-0.92)	0.46 (0.30-0.71)	<0.01
Model 2	1.00	0.89 (0.65-1.22)	0.88 (0.63-1.24)	0.72 (0.49-1.05)	0.52 (0.33-0.82)	<0.01
Model 3	1.00	0.96 (0.70-1.32)	0.97 (0.68-1.38)	0.77 (0.51-1.18)	0.53 (0.32-0.86)	<0.01
Supplement users (n=1,205)						
Magnesium intake, mg/1000 kcal; Median (interquartile range)	123.6 (112.6-133.0)	151.0 (146.1-156.0)	172.6 (166.6-179.0)	196.0 (188.9-203.7)	248.8 (233.3-290.4)	
No. of events / participants	32 / 241	16 / 241	17 / 241	6 / 241	6 / 241	
Model 3	1.00	0.66 (0.33-1.30)	0.70 (0.34-1.44)	0.24 (0.09-0.67)	0.32 (0.10-0.96)	0.01
Supplement non-users (n=3,292)						
Magnesium intake, mg/1000 kcal; Median (interquartile range)	97.0 (89.4-102.0)	115.1 (111.0-119.0)	130.1 (126.5-134.2)	149.7 (144.2-154.5)	180.0 (169.3-196.6)	
No. of events / participants	59 / 658	58 / 659	54 / 658	45 / 659	37 / 658	
Model 3	1.00	0.96 (0.66-1.41)	0.79 (0.53-1.18)	0.79 (0.50-1.26)	0.74 (0.44-1.26)	0.21

* All models were constructed by Cox proportional hazards model. The median magnesium level in each quintile was created for the trend tests. **Model 1:** adjustment for age (continuous), gender, ethnicity (African American, Caucasian) and study center; **model 2:** model 1 with additional adjustment for education (continuous), smoking status (never, former, current), alcohol consumption (none, 0.1-9.9, 10-19.9, ≥ 20 g/d), physical activity (quintiles), family history of diabetes, body mass index (<25, 25-29.9, ≥ 30 kg/m²), systolic blood pressure (continuous) and total energy intake (quintiles); **model 3:** model 2 with additional adjustment for dietary intakes (quintiles) of saturated fat and crude fiber.

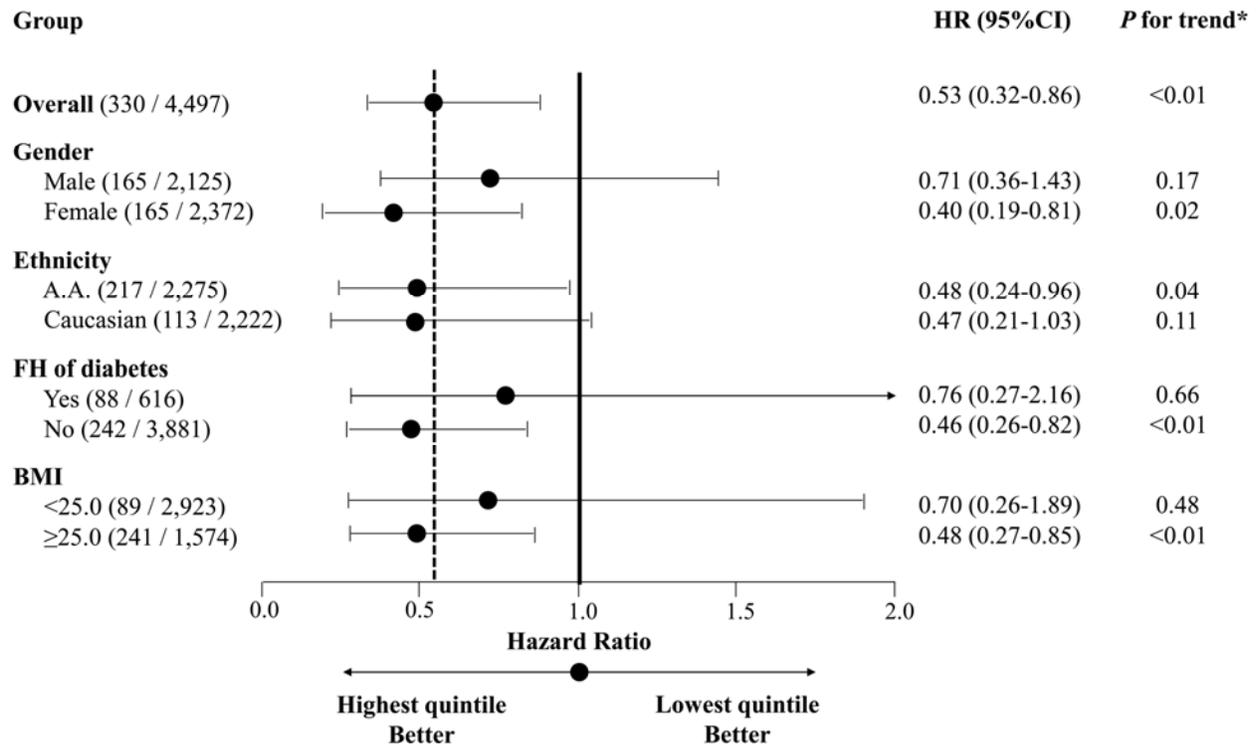

Table 3. Multivariable-adjusted associations of total magnesium intake (quintiles) with inflammatory markers and homeostasis model assessment of insulin resistance

	Quintiles of total magnesium intake					<i>P</i> for trend
	1 (lowest)	2	3	4	5 (highest)	
Hs-CRP (n = 4,157)						
Median (mg/l)	1.60	1.37	1.27	1.00	0.86	
Model 1	0	-0.071 (-0.153, 0.012)	-0.008 (-0.093, 0.077)	-0.151 (-0.245, -0.057)	-0.270 (-0.368, -0.172)	<0.01

HOMA-IR (n = 4,239)						
Median	2.66	2.63	2.50	2.36	2.11	
Model 1	0	-0.046 (-0.081, -0.012)	-0.040 (-0.077, -0.003)	-0.085 (-0.123, -0.047)	-0.153 (-0.195, -0.112)	<0.01
Model 2	0	-0.045 (-0.077, -0.013)	-0.036 (-0.070, -0.002)	-0.068 (-0.103, -0.033)	-0.122 (-0.160, -0.084)	<0.01
Model 3	0	-0.046 (-0.078, -0.013)	-0.036 (-0.071, -0.000)	-0.065 (-0.102, -0.029)	-0.117 (-0.157, -0.077)	<0.01

Data are β coefficients (95% CIs). A logarithmic transformation was used to improve the normality of distribution for dependent variables. Generalized estimating equations were used for repeated measurements of hs-CRP, fibrinogen and HOMA-IR and general linear regression model was used for IL-6. The median magnesium level in each quintile was created for the trend tests. The adjusted covariates in the models were the same as those listed in Table 2.

Figure legend

Figure 1. Hazard ratios (95% confidence intervals) for incident diabetes in participants in the highest magnesium intake quintile compared with those in the lowest quintile, stratified by gender, ethnicity, family history of diabetes, and body mass index.

A.A., African American; FH, family history; BMI, body mass index. Data in the bracket in the group column were number of events / numbers of participants. The adjusted covariates in the models were the same as those of the model 3 listed in Table 2.

* Continuous variables using the median value in each quintile were created for trend tests.
